Penile neoplasms;
Kaposi's sarcoma

Abstract We present the case of an HIV-negative man with asymptomatic penile erythematoviolaceous papules associated with similar slightly verrucous papules in the interdigital space of the right foot. A biopsy of the penile lesion confirmed Kaposi's sarcoma. No other causes of immunosuppression were observed. Kaposi's sarcoma penile lesions are rare in HIV-negative individuals but it should also be considered in the differential diagnosis. Careful follow-up is recommended.

Case report

A middle-aged heterosexual Caucasian man of Italian origin was seen at a dermatology practice with asymptomatic lesions on the penis and without general symptoms. He

reported having a regular sexual partner for several years, as well as occasional partners, with whom he reported regularly using condoms. He had been adequately treated for syphilis five years earlier and had no other significant health problems.

Physical examination indicated erythematoviolaceous papules on the corona of the glans on the ventral surface of the penis (Fig. 1). A general examination of the skin evidenced similar lesions in the first interdigital space of the right foot, one of which was slightly verrucous (Fig. 2). The histopathological study of one of the penile lesions revealed a fusocellular proliferation with elongated and branched

vessels, hemorrhage, frequent mitoses, and few cellular atypias (Fig. 3).

What is your diagnosis?

- a) Molluscum contagiosum
- b) Genital warts
- c) Kaposi sarcoma
- d) Pyogenic granuloma

In greater detail, gaps with extravasated erythrocytes, few atypical cells, and several mitoses can be observed (Fig. 3). The immunohistochemical study detected nuclear positivity for antibodies against the Kaposi's sarcoma-associated herpesvirus (Fig. 3, inset). Contrary to clinical expectations, fourth-generation ELISA tests, performed at a two-month interval, were negative on both occasions. To better discard HIV infection, viral load was measured by a PCR test, which was also negative. Serology for hepatitis B and C was negative; FTA-Abs was positive and VDRL was non-reactive. Computed tomography of chest and abdomen did not show any lesions. Cryotherapy sessions were unsuccess-

ful. The lesions were surgically excised; the recurrence of one small lesion was observed after eight months of follow-up. As no additional manifestations were observed, a new excision was performed and a strict follow-up was recommended.

Discussion

Kaposi's sarcoma (KS) is a spindle cell neoplasm described in 1872 by Moritz Kaposi. It is a rare disease that is usually

observed in men over 60 years of age, especially of Mediterranean and/or Jewish origin. It commonly appears in the lower limbs, in which it remains indolent. Metastases and deaths are rarely reported.¹ Three other forms have been described. The aggressive endemic form is found in Africa and was first described in 1914. The iatrogenic form affects transplant recipients (mainly in cases of solid organ transplants and immunosuppressed patients), especially those who use corticosteroids for long periods. The AIDS-related form (epidemic form) was identified among men who had sex with men in the early 1980s.² In 1990, through evaluations of epidemiological information, it was inferred that the etiologic agent of KS would be a sexually transmitted virus, which was confirmed in 1994 by Chang et al.³ This form of the disease has a variable course, but it can be very aggressive, leading to spread and death. Lesions on the genitals and/or the oral cavity are usually identified as an initial manifestation of AIDS. The use of antiretroviral therapy has reduced its global incidence and often reverses the course of KS.⁴

The Kaposi's sarcoma-associated herpesvirus is a gamma-herpesvirus (HHV-8). Infection is considered necessary, but not sufficient, for the development of this sarcoma. Its transmission through saliva or other body fluids is accompanied by an unpredictable period of latency that is similar in other herpesviruses.⁵ In endemic regions, such as Africa, over 80% of adolescents may have antibodies to the virus. In the general population of northern Europe and the United States, the serum prevalence is less than 5%; however, in homosexual or bisexual men, a serum prevalence of up to 25% has been described. In individuals with normal immunity, its presence rarely leads to Kaposi sarcoma.

Penile lesions of KS are rare in HIV-negative heterosexual individuals, which highlights the relevance of the present case report. Few cases of KS of the penis among patients without HIV infection have been published in the literature.⁶ The authors' initial belief was that the patient had an otherwise asymptomatic infection, an assumption that was ruled out after laboratory investigation. Despite the need for a high level of suspicion regarding HIV infection when assessing patients with KS penile lesions, careful pre-test counseling is required to avoid jumping to conclusions about the diagnosis of HIV infection and its emotional consequences.
